reflect drought and flood events.

1. Introduction

Carbon isotopes (δ^{13} C) of cave calcites are an alternative index in paleoclimate and paleoenvironment reconstruction studies of stalagmites. These have drawn broad attention for many years [\(Hendy,](#page-7-0) [1971;](#page-7-0) [Bar-Matthews et al., 1996,](#page-6-0) [1999](#page-6-1); [Baker et al., 1997;](#page-6-2) [McDermott,](#page-7-1) [2004;](#page-7-1) [Fohlmeister et al., 2011](#page-6-3); [Frisia et al., 2011\)](#page-6-4) because of their important potential for interpreting ecosystem and climate changes ([Huang et al., 2016](#page-7-2)).

Stalagmite δ^{13} C is affected by air, soil, vegetation, the epikarst zone, and the cave, all of which lead to complex carbon sources and numerous contributing factors for the change of stalagmite δ^{13} C. The overlying vegetation type (C3/C4 vegetation) determines the δ^{13} C of soil CO2 ([Dorale et al., 1992](#page-6-5), [1998;](#page-6-6) [Denniston et al., 2000\)](#page-6-7). Surface temperature and rainfall affect the $CO₂$ productivity of the overlying soil of caves [\(Hesterberg and Siegenthaler, 1991;](#page-7-3) [Amundson et al.,](#page-6-8) [1998;](#page-6-8) [Genty et al., 2003;](#page-6-9) [Moreno et al., 2010](#page-7-4)). The openness of the epikarst zone determines the proportion of carbon from different sources (such as the atmosphere, soil, air, and the bedrock) in drip

water and cave deposits [\(Genty et al., 2001](#page-6-10), [2003;](#page-6-9) [Kong et al., 2005](#page-7-5); [Spötl et al., 2005;](#page-7-6) [Cruz et al., 2006](#page-6-11); [Cosford et al., 2009;](#page-6-12) [Moreno et al.,](#page-7-4) [2010\)](#page-7-4). Cave air $pCO₂$ affects the degassing rate of drip water and the growth rate of cave deposits ([Spötl et al., 2005;](#page-7-6) [Dreybrodt and Scholz,](#page-6-13) [2011;](#page-6-13) [Deininger et al., 2012\)](#page-6-14). Prior calcite precipitation (PCP), which is the result of $CO₂$ degassing from groundwater in the epikarst zone in dry climatic periods is also an important factor that can increase the δ^{13} C values of the dissolved inorganic carbon (DIC) in cave drip water $(\delta^{13}C_{\text{DIC}})$ [\(Baker et al., 1997](#page-6-2); [Verheyden et al., 2000](#page-7-7); [Fairchild and](#page-6-15) [Treble, 2009](#page-6-15)). Given these factors, the difference in δ^{13} C values of different stalagmites in the same cave, during the same time period, can be 4–10‰ ([Linge et al., 2001;](#page-7-8) Serefi[ddin et al., 2004\)](#page-7-9), which makes it difficult to correctly interpret climate and environmental information from stalagmite δ^{13} C.

The factors mentioned above are related to climate change and are affected by differences in epikarst zones and caves. In addition, most soil $CO₂$ comes from the respiration of plant roots or is released by microorganisms during the decomposition of organic debris ([Dreybrodt, 1988;](#page-6-16) [Hess and White, 1993](#page-7-10); [Gillieson, 1996;](#page-7-11) [Murthy et al.,](#page-7-12)

[2003;](#page-7-12) [Baldini et al., 2008;](#page-6-17) [Bond-Lamberty and Thomson, 2010](#page-6-18)). Ecosystem and climate warming experiments [\(Luo et al., 2001](#page-7-13); [Bronson](#page-6-19) [et al., 2008\)](#page-6-19), model analysis [\(McGuire et al., 1995](#page-7-14); [Raich et al., 2002](#page-7-15)), and biodynamics studies have shown that plant root respiration and the activity of microorganisms in soil are mainly affected by climate change ([Davidson and Janssens, 2006\)](#page-6-20).

Cave simulation and monitoring plays an important role in understanding the factors that control stalagmites, and in further analyzing the transmission process and mechanism of the δ^{13} C signal in karst cave systems ([Genty and Massault, 1999](#page-6-21); [Mickler et al., 2004](#page-7-16), [2006](#page-7-17); [Spötl](#page-7-6) [et al., 2005](#page-7-6); [Fairchild et al., 2006;](#page-6-22) [Genty and Dominique, 2008;](#page-6-23) [Mattey](#page-7-18) [et al., 2008;](#page-7-18) [Deininger et al., 2012;](#page-6-14) [Luo et al., 2013;](#page-7-19) [Dreybrodt and](#page-6-24) [Deininger, 2014](#page-6-24)). Through simulating cave temperature, the water drip rate, CO₂ degassing in drip water, and the residence time of drip water on top of a stalagmite, researchers can study the effects of these factors on the δ^{13} C of cave deposits [\(Baldini et al., 2006](#page-6-25); [Mühlinghaus et al.,](#page-7-20) [2007,](#page-7-20) [2009;](#page-7-21) [Whitaker et al., 2009;](#page-7-22) [Dreybrodt and Scholz, 2011](#page-6-13); [Deininger et al., 2012\)](#page-6-14). Cave monitoring can lead to the understanding of the isotope fractionation process between drip water and active carbonate deposits [\(Verheyden et al., 2008;](#page-7-23) [Li et al., 2011b](#page-7-24); [Tremaine](#page-7-25) [et al., 2011;](#page-7-25) [Riechelmann et al., 2013](#page-7-26)). The systematic investigation of factors such as surface temperature, rainfall, vegetation type and distribution, and soil and cave air $pCO₂$ can help in the interpretation of the effects of processes in the epikarst zone on the δ^{13} C values of cave drip water and active deposits ([Whitaker et al., 2009](#page-7-22); [Li et al., 2012](#page-7-27); [Luo et al., 2013](#page-7-19); [Feng et al., 2014](#page-6-26); [Meyer et al., 2014\)](#page-7-28).

In order to gain a better understanding of the sources of cave $CO₂$ and the transmission mechanism of $CO₂$ from the epikarst zone to the cave, as well as the relationship between δ^{13} C of drip water and cave pCO2, a multi-parameters monitoring program has been underway at Furong Cave, Chongqing, southwest China, since 2005. [Li et al. \(2012\)](#page-7-27) analyzed the differences in seasonal DIC δ^{13} C in drip water and pool water. Differences were attributed to variable degrees of $CO₂$ degassing in winter and summer. However, the main factors affecting seasonal variation in cave pCO_2 and the sources of cave CO_2 were not discussed in this earlier paper. This study also had a short monitoring time (from March 2009 to June 2010). In the current study, based on the monitoring data of surface temperature, rainfall, soil/cave air $pCO₂$, and $\delta^{13}C_{\text{DIC}}$ values of drip water measured at Furong Cave from 2009 to 2016, we discuss the relationships between both cave air $pCO₂$ and drip water $\delta^{13}C_{\text{DIC}}$ and surface hydrological and thermal conditions on the annual time scale, and analyze the effect of regional drought events on the $\delta^{13}C_{\text{DIC}}$ of cave drip water. The data presented here provides an opportunity to explore the link between rainfall and both soil $pCO₂$ and cave $pCO₂$.

2. Study area

Furong Cave (29°13′ N, 107°54′ E) is located near the Furong River at Jiangkou Town, Wulong County, Chongqing, southwest China. It is approximately 5 km away from the confluence of the Furong and Wujiang Rivers [\(Fig. 1A](#page-2-0)). The region has a typical subtropical humid monsoon climate, affected by both the Asian southeast summer monsoon and the Asian southwest summer monsoon. The annual mean temperature and precipitation was 17.9 °C and 1080 mm, respectively, during 2005–2016, as recorded at the Wulong weather station. The precipitation from May to October accounts for 70–80% of the precipitation for the entire year [\(Li et al., 2011b\)](#page-7-24). The overlying strata are Mid-Cambrian limestone and dolomite. The surface vegetation cover is 95%, and mostly consists of trees and shrubs. The soil is affected by slope gradient, slope direction, and surface vegetation cover, and its thickness is 20–100 cm [\(Li et al., 2012](#page-7-27)).

The cave entrance of the Furong Cave is at an elevation of 480 m. The total cave length is approximately 2800 m. The width and height are 30–50 m, each. The current developed area is approximately 1800 m long. There is only one entrance and the exit is an artificial

tunnel excavated in 1996, with a length of 180 m and a height of 3 m. The cave air temperature is 16.0–16.3 °C and the humidity in the Great Hall, which is located about 1500 m from the cave entrance, is 95–100% year round [\(Li et al., 2011b\)](#page-7-24) [\(Fig. 2\)](#page-2-1).

3. Sample collection and experimental analysis

A HOBO miniature meteorological monitor, manufactured by ONSET (USA), was installed outside the Furong Cave, about 50 m from the entrance, to monitor the air temperature (range 40–75 °C, precision \pm 0.2 °C), humidity (range 0–100%, precision \pm 2.5%), and precipitation (resolution 0.2 mm, precision \pm 1.0%). We selected five soil profiles along the two sides of the valley above the Furong Cave where CO_2 -monitoring apparatuses were installed [\(Fig. 1](#page-2-0)B). Their labels (depths) were SA (50 cm), SB (20 cm), SC (50 cm), SD (50 cm), and SE (50 cm), respectively. They were all located at the interface between the bedrock and the soil. We used an AP-20 $CO₂$ sampler manufactured by Komyo Rikagaku Kogyo K.K. and a 126SA testing tube to measure the soil $CO₂$ concentration monthly. The measurement range was a 0.1–2.6% volume concentration.

An automatic thermometer was placed in the Great Hall (StowAway TidbiT Temp Logger, Onset Computer Corporation model TBI32- 20 + 50, temperature range −20–70 °C, precision ± 0.2 °C) to record the cave temperature every 2 h, from November 2006 to October 2007 ([Li et al., 2011b\)](#page-7-24). Six sites (#2, #4, MP1-MP4) inside the cave were chosen to measure cave air $pCO₂$ once a month. Five sites (#2, #4, MP1-MP3) were located in the Great Hall, and MP4 was in the corridor, approximately 600 m from the entrance ([Fig. 2\)](#page-2-1). We used a Testo535 infrared CO₂ meter manufactured by Testo, Germany, to measure the air $CO₂$ concentration inside and outside of the cave (#5) (range of 0–9999 ppmv; measurement precision greater than 2%). We used a Testo635 temperature and moisture meter to measure the air temperature and humidity at every monitoring site inside and outside the cave (temperature range −40–150 °C, precision ± 0.2 °C; relative humidity range 0–100%, precision \pm 0.1%).

We selected five drip water monitor sites (MP1∼MP5) inside the Furong Cave ([Fig. 2](#page-2-1)) and drip water was collected monthly from 2009 to 2016. For collection of drip water samples, we used clean PE sample bottles that had been rinsed in 1:1 HCl and washed with deionized water. To avoid isotope fractionation caused by microorganisms, 0.2 mL saturated $HgCl₂$ solution was added into the samples used for δ^{13} C_{DIC} measurements (20 mL). The samples were sealed, brought back to our laboratory, and stored at 5 °C for analysis. The $\delta^{13}C_{\text{DIC}}$ of drip water analyses were completed at the Geochemistry and Isotope Laboratory of the Southwest University. Analyses were performed using a Delta-V-Plus Mass Spectrometer connected to a Gas Bench pretreatment apparatus. The analysis precision was greater than 0.2% (1 σ). The $\delta^{13}C$ results are reported using V-PDB as the reference.

4. Results

4.1. Regional temperature, precipitation, and air $pCO₂$

For this study, the monitoring period was from January 2009 to December 2016. Monthly mean temperature and precipitation are shown for each year ([Fig. 3E](#page-2-2) and F). Monthly temperature data reveal low values in December and January (mean $T = 7.8 \pm 1.3 \degree C$), and high values in July and August (mean T = 28.0 \pm 0.9 °C). The lowest monthly mean temperature (4.3 °C) was observed in January 2011 ([Fig. 3E](#page-2-2)).

The lowest annual precipitation sum (751 mm) was recorded in 2009, while the highest value occurred in 2016 (1498 mm). The lowest monthly rainfall (4–19 mm) was primarily in January and February, except in 2016 (December). However, the highest monthly precipitation (154–423 mm) was in a different month every year; highest monthly precipitations were observed from April to July and September

Fig. 1. Geographical location of the study area. Location of the Furong Cave (solid circle) in Chongqing City, southwest China (A). Five soil monitoring sites, SA-SE (black solid triangles), overlying the Furong Cave (B). The black shadow indicates the Furong Cave; contours with elevations for this area are shown.

Fig. 2. Sketch map of the Furong Cave. Distribution of the monitoring sites: MP1-MP5 for drip water (black solid stars); $#2$ and $#4$ for pool water (black solid dots) (after [Li et al., 2011b](#page-7-24)); site #5 for air pCO_2 monitoring outside the cave. The dashed line shows the tour route and the Great Hall indicates the inner part of the cave.

([Fig. 3](#page-2-2)F). Meanwhile, it was observed that the monthly rainfall was less than 50 mm in July (41 mm) 2011, August (44 mm) 2012, and July (19 mm) 2013, when the monthly mean temperature was higher than 27 °C ([Fig. 3E](#page-2-2) and F). This is characteristic of typical summer droughts.

The air $pCO₂$ outside the Furong Cave was measured from May 2010 to November 2016, except for in May 2015, and July and November 2016, due to problems with the instrumentation. The mean air $pCO₂$ was 447 \pm 75 ppmv. The monthly mean air $pCO₂$ varied from 392 ppmv to 504 ppmv; results did not show significant annual or seasonal variation patterns. The highest monthly air $pCO₂$ (690 ppmv) was observed in November 2013 and the lowest (262 ppmv) was recorded in August 2011 ([Fig. 3](#page-2-2)D). The variation range in air $pCO₂$ during 2010–2013 was significantly greater than that during 2014–2016 ([Fig. 3D](#page-2-2)).

4.2. Soil $pCO₂$

The soil $pCO₂$ overlying the Furong Cave showed significant seasonal variation. During April∼October, high values for soil pCO₂ were observed, with a mean value of 5700 ppmv. Soil $pCO₂$ reached its peak in July and August. From November to March, soil $pCO₂$ decreased and

Fig. 3. Comparisons of $\delta^{13}\rm{C}_{\rm{DIC}}$ of drip water from the Furong Cave (A), $p\rm{CO}_2$ of cave air (B), soil air (C), and air outside of the cave (D), monthly average temperature (E), and monthly precipitation (F) of Wulong County during the monitoring period of 2009–2016.

Fig. 4. Comparisons of average $\delta^{13}C_{\text{DIC}}$ of drip water (A), average pCO₂ of cave air (B) and soil air (C), monthly average temperature (D), and annual precipitation (E). The gray dashed lines with arrows denote the trends for changes in the monitoring parameters. In general, from 2010 to 2011, decreasing annual precipitation is consistent with higher $\delta^{13}C_{\text{DIC}}$ in drip water and lower air pCO_2 in the cave and soil. From 2013 to 2016, increasing annual precipitation resulted in lower $\delta^{13}C_{\text{DIC}}$ in drip water and higher air pCO_2 in the cave and soil.

was generally lower than 2000 ppmv, with a mean value of 1300 ppmv. Soil $pCO₂$ reached its annual minimum in January and February ([Fig. 3](#page-2-2)D). The monthly difference in soil $pCO₂$ was large. The maximum in summer was 16644 ppmv (SE, July 2015), and the minimum in winter (November to March) was less than 500 ppmv.

There was significant annual variation in characteristics of soil $pCO₂$. For example, the maximum $pCO₂$ values at the SE soil monitoring site in 2011 and 2015 were 9024 ppmv and 16644 ppmv, respectively ([Fig. 3](#page-2-2)C). The mean $pCO₂$ values of five sites (SA-SE) in 2011 and 2013 were 3023 ppmv and 3160 ppmv, respectively, while the mean values were 4138 ppmv and 4858 ppmv in 2014 and 2015, respectively. After 2013, the peak of the mean soil $pCO₂$ values showed a gradual increasing trend ([Fig. 4](#page-3-0)C).

4.3. Cave air $pCO₂$

The cave air pCO_2 at the five monitoring sites (#2, #4, MP1-MP3) in the Great Hall showed significant seasonal variation from 2010 to 2016. Low- $pCO₂$ values were observed in December to April. The mean value was 1030 \pm 255 ppmv. High-pCO₂ values were observed between May and November; the mean value was 1578 ± 256 ppmv [\(Fig. 3B](#page-2-2)). The mean pCO_2 values of five sites (#2, #4, MP1-MP3) inside the cave were relatively consistent (1353–1432 ppmv), indicating that air $CO₂$ in the Great Hall was well mixed ([Fig. 2](#page-2-1)). Temperature and humidity

Fig. 5. The positive linear relationship between average soil and air $pCO₂$ and monthly precipitation (A) and monthly average temperature (B) over the Furong Cave, showing that precipitation and temperature are important factors determining the production of soil $CO₂$. However, during the summer and autumn seasons, precipitation is the decisive factor for the production of soil CO₂. See the text for details.

monitoring data also showed that the inside cave environment was stable ([Li et al., 2011b](#page-7-24)).

The $pCO₂$ values at the MP4 monitoring site also showed significant annual and seasonal variation patterns. However, the magnitude of the variation at this site was larger than that at the other sites. From December to April, the mean $pCO₂$ at MP4 was 1321 \pm 425 ppmv, and from May to November, the mean $pCO₂$ was 1624 \pm 549 ppmv. Furthermore, several months showed $pCO₂$ concentrations higher than 2500 ppmv, which is significantly higher than the $pCO₂$ values measured at the other sites at the same times ([Fig. 3B](#page-2-2)).

4.4. Drip water $\delta^{13}C_{\text{DIC}}$

The variation in $\delta^{13}C_{\text{DIC}}$ values of drip water in the Furong Cave ranged from 1.2‰ to −14.7‰, from 2010 to 2016 [\(Fig. 3A](#page-2-2)). The $\delta^{13}C_{\text{DIC}}$ values from all sites (MP1-MP5, [Fig. 3A](#page-2-2)) showed similar variation patterns, indicating that the carbon source for drip water in the Furong Cave, and the factors that affect the $\delta^{13}C_{\text{DIC}}$ of drip water, were similar. The mean $\delta^{13}C_{\text{DIC}}$ values of drip water (MP1-MP5) in the Furong Cave displayed seasonal variability, with lower values during the months from May to November (the summer-autumn half of the year) and higher values during the months from December to April (the winter-spring half of the year) ([Figs. 4A and 6](#page-3-0)). The mean $\delta^{13}C_{\text{DIC}}$

Fig. 6. Seasonal arithmetic mean of drip water $\delta^{13}C_{\text{DIC}}$ for all sites in the Furong cave. The empty and solid squares indicate the mean $\delta^{13}C_{\text{DIC}}$ of drip water for the summer-autumn and winter-spring half of the year, respectively. The error bars indicate the standard deviation of drip water $\delta^{13}C_{\text{DIC}}$ values at different sites.

values of the summer-autumn and winter-spring halves of the year were −9.5 ± 2.3‰ and −8.7 ± 2.6‰, respectively. For 2011–2013 specifically, the mean $\delta^{13}C_{\text{DIC}}$ values in the winter-spring half of the year in 2011, 2012, and 2013 were −8.7 ± 3.2‰, −6.0 ± 2.0‰, and −6.0 ± 1.1‰, respectively. In the same period of 2009–2010 and 2014–2016, the values were lower than -9.0% [\(Fig. 6\)](#page-4-0). The same situation was evident in the summer-autumn half of the year ([Fig. 6](#page-4-0)). The $\delta^{13}C_{\text{DIC}}$ values of drip water showed an increasing trend in 2010–2012; however, they gradually decreased from 2012 to 2016 ([Figs. 3A, 4A and 6](#page-2-2)).

5. Discussion

5.1. Relationships between soil $pCO₂$, temperature, and precipitation in the Furong Cave

In summer, from June to August, the Chongqing region is frequently affected by the west Pacific subtropical high (WPSH) and is prone to summer drought; during this time it experiences high temperature and low precipitation, as evident in the data from July 2011, August 2012, and July 2013 (discussed above in section [4.2](#page-2-3)) ([Fig. 3](#page-2-2)F). Consistent with the precipitation data, soil air $pCO₂$ at all sites (SA-SE) was not significantly decreased, and the mean value was more than 6000 ppmv ([Fig. 3](#page-2-2)C). In other words, the change in soil air $pCO₂$ lags behind the change in precipitation above the Furong Cave. This phenomenon is consistent with the findings of previous studies. For example, [Reichstein et al. \(2003\)](#page-7-29) suggested that, on average, 40% of maximal (not water-limited) soil respiration can be maintained in months of zero precipitation.

Temperature and humidity are the most important factors that determine the bioactivity in soils, and precipitation makes a significant contribution to humidity. [Raich and Schlesinger \(1992\)](#page-7-30) built the T&P Model to describe the relationship between annual soil respiration rates and mean annual air temperatures and precipitation; the correlation coefficients were $R_t^2 = 0.42$ and $R_p^2 = 0.34$, respectively. Because the $pCO₂$ variation characteristics of the overlying soil of the Furong Cave showed consistency at all five monitoring sites (SA-SE) [\(Fig. 3](#page-2-2)C), we calculated the arithmetic monthly mean of soil $pCO₂$ and analyzed the correlations between mean soil $pCO₂$ and temperature and precipitation ([Fig. 5\)](#page-3-1). The correlation coefficients between monthly soil $pCO₂$ and monthly mean temperature and precipitation were $R_T^2 = 0.69$ (ρ < 0.001) and R_p² = 0.28 (ρ < 0.001). It is clear that local

temperature and precipitation both significantly affect the monthly $pCO₂$ in the overlying soil of the Furong Cave.

On an annual time scale, the $pCO₂$ of the overlying soil of the Furong Cave showed variation similar to that of the total annual precipitation ([Fig. 4](#page-3-0)C and E). From 2010 to 2011, the annual precipitation decreased, and the peak value of soil $pCO₂$ also decreased significantly [\(Fig. 3](#page-2-2)C). From 2012 to 2016, the annual precipitation gradually increased, and the soil $pCO₂$ also showed an overall increasing trend [\(Fig. 3C](#page-2-2)). However, the variation in mean monthly soil $pCO₂$ did not show a significant correlation with that of the monthly mean temperature ([Fig. 4C](#page-3-0) and D), indicating that on the annual scale, annual total precipitation more strongly affected soil $pCO₂$ than temperature did.

5.2. Analysis of the factors that influence cave air $pCO₂$

Cave $CO₂$ originates from multiple sources: (1) $CO₂$ produced by soil biological processes ([Knorr et al., 2005](#page-7-31); [Davidson and Janssens, 2006](#page-6-20); [Whitaker et al., 2009;](#page-7-22) [Frisia et al., 2011;](#page-6-4) [Breecker et al., 2012\)](#page-6-27); (2) CO₂ produced by the respiration of cave microbes; (3) $CO₂$ in the epikarst zone released, in the form of molecules, to the cave via rock fractures due to the density of $CO₂$ being 1.5 times that of air ([Ek and Gewelt,](#page-6-28) [1985;](#page-6-28) [Berger, 1988](#page-6-29); [Bourges et al., 2001](#page-6-30); [Badino, 2009\)](#page-6-31); (4) CO₂ released by decomposition of cave organic matter; and (5) geothermal CO2 via faults and fractures ([Mattey et al., 2010](#page-7-32); [Faimon et al., 2012](#page-6-32)). In most cases with no ventilation, cave air $pCO₂$ levels can only increase as high as soil air $pCO₂$ ([Baldini, 2010](#page-6-33)). [Smith \(1999\)](#page-7-33) suggested that higher cave air $pCO₂$ levels could theoretically be reached through the consumption of atmospheric O_2 and the production of CO_2 through microorganism metabolism, or through the addition of high levels of geothermally-derived CO_2 . Though cave pCO_2 varied from 500 to 3000 ppmv in the Furong Cave [\(Fig. 3](#page-2-2)B), the values were lower than soil air $pCO₂$ ([Fig. 3C](#page-2-2)). There is no fault in the lower strata of the Furong Cave; thus, the $CO₂$ source cannot be (2), (4), or (5). Sources (1) and (3) are essentially identical; $CO₂$ originates primarily from the high-concentration soil $CO₂$ produced by soil biological activity and organic matter decay ([Fig. 3C](#page-2-2)).

Due to the consistent cave $pCO₂$ variation at different monitoring sites (#2, #4, MP1∼MP3) in the Furong Cave ([Fig. 3B](#page-2-2)), we calculated the arithmetic mean of cave air $pCO₂$ and compared it with the mean of soil pCO_2 [\(Fig. 4B](#page-3-0) and C). Although both soil and cave pCO_2 showed seasonal variation patterns, soil $CO₂$ was more sensitive and directly responded to the change in local temperature and precipitation. Its seasonal variation magnitude could be more than 10,000 ppmv. The magnitude of the seasonal variation in cave air $pCO₂$ was 1000–2000 ppmv, which is far less than that of soil $pCO₂$ [\(Fig. 4B](#page-3-0) and C). The month with the maximum soil $pCO₂$ corresponded to the month with the highest precipitation in summer and autumn [\(Fig. 3](#page-2-2)C and F), while peak values of cave $pCO₂$ were measured in October and November ([Figs. 3B and 4B](#page-2-2)). Cave $CO₂$ mainly comes from the degassing of groundwater, which directly reflects the change in precipitation ([Li](#page-7-34) [et al., 2013](#page-7-34)), and is dissolved in a large amount of soil $CO₂$. Groundwater flows through the 300–500 m thick bedrock overlying the Furong Cave ([Li et al., 2011b\)](#page-7-24). Therefore, cave $pCO₂$ lags 1–2 months behind changes in surface hydrological and thermal conditions and soil $pCO₂$ ([Huang et al., 2016](#page-7-2)).

Average cave air $pCO₂$ showed variation characteristics similar to that of soil pCO_2 and precipitation on the inter-annual scale. From 2010 to 2011, the amount of rainfall decreased and was accompanied by a decrease in soil/cave air $pCO₂$. In 2012, the annual precipitation increased, as did the soil and cave $pCO₂$. There was a gradual increase in precipitation from 2013 to 2016, and the soil and cave $pCO₂$ increased in the same way [\(Fig. 4](#page-3-0)B, C, 4E). Precipitation is clearly an important factor affecting $pCO₂$ in the Furong Cave. The direct influence of atmosphere temperature on cave air $pCO₂$ is insignificant at the interannual scale [\(Fig. 4](#page-3-0)B and D) ([Baldini et al., 2008](#page-6-17)).

The MP4 site showed a higher $CO₂$ concentration and a greater

magnitude of variability. Although atmosphere environment and soil air pCO_2 are the primary factors that control pCO_2 in the cave, previous studies have shown that, at various locations inside the cave, different cave shapes can cause differences in cave airflow and degree of cave air mixing, which ultimately leads to significantly different $CO₂$ concentrations at various locations in the same cave ([Bourges et al., 2001](#page-6-30); [Denis et al., 2005](#page-6-34); [Benavente et al., 2010;](#page-6-35) [Wong and Banner, 2010](#page-7-35)). The height, width, and length of the Great Hall where sites #2, #4, and MP3 are located, are 21 m, 32 m, and 100 m, respectively. Furthermore, this huge chamber was closed to tourists and the tour route was changed after the Wenchuan Earthquake occurred in the Sichuan province in southwest China in 2008. The height and width of the channel where the MP4 site is located is 8 m and 25 m, respectively; the MP4 site is near the tour path [\(Fig. 2\)](#page-2-1). All tourists must pass the MP4 site to complete the tour process. Studies illustrate that after 5 min, human presence in a cave raises the $pCO₂$ by 30% (assuming an original $pCO₂$) of 0.4%) [\(Ek and Gewelt, 1985](#page-6-28)). Therefore, more $CO₂$ from human breathing accumulated at MP4, leading to higher $CO₂$ concentrations and a greater magnitude of variation.

5.3. Effect of precipitation on the $\delta^{13}C_{\text{DIC}}$ of cave drip water

The carbon in cave drip water originates primarily from $CO₂$ released by the respiration of vegetation roots, $CO₂$ produced by the decomposition of soil organic matter, and groundwater CO_3^2 ⁻ from bedrock dissolution. The values of $\delta^{13}C$ for these carbon sources vary significantly ([Hendy, 1971](#page-7-0); [Genty et al., 2001](#page-6-10); [Mickler et al., 2004](#page-7-16); [Spötl et al., 2005;](#page-7-6) [Fairchild et al., 2006;](#page-6-22) [Frisia et al., 2011](#page-6-4)). According to [Li et al. \(2012\)](#page-7-27), the main vegetation above the Furong Cave is C3 plants with an average δ^{13} C of −32‰, whereas the average δ^{13} C of the soil total organic carbon is -22% , and the range of $\delta^{13}C$ in bedrock is −2.6–0.1‰. In the process of infiltration, changes in conditions such as temperature, precipitation, pH value, and transport path lead to significant variation in the ratios of carbon from different sources in groundwater, where the ratio of bedrock carbon is between 0 and 50% ([Garrels and Christ, 1965;](#page-6-36) [Hendy, 1970](#page-7-36), [1971;](#page-7-0) [Salomons and Mook,](#page-7-37) [1986;](#page-7-37) [Schwarcz, 1986](#page-7-38); [Genty et al., 2001](#page-6-10)). Thus, the $\delta^{13}C_{\text{DIC}}$ values of cave drip water fluctuate significantly under different climate conditions.

Over the course of a year, during the transition from the summer and autumn seasons, characterized by more precipitation, to the winter and spring seasons, characterized by less precipitation, the $\delta^{13}C_{\text{DIC}}$ of drip water increases from \lt -10‰ to $>$ -6‰ ([Fig. 3](#page-2-2)A). The annual variability in the $\delta^{13}C_{\text{DIC}}$ of drip water follows that of the total precipitation during the same year [\(Fig. 4A](#page-3-0) and E). The annual precipitation was less than 1000 mm in 2009–2011 and more than 1100 mm in 2012–2016, with an increasing trend [\(Fig. 4](#page-3-0)E). The average $\delta^{13}C_{\text{DIC}}$ value of drip water gradually became heavier from 2010, and reached a maximum in the winter of 2012, before gradually decreasing from 2013 ([Fig. 4A](#page-3-0)).

During winter and spring, when there is little precipitation and relatively low temperatures [\(Fig. 3](#page-2-2)E and F), the respiration rate of vegetation roots and the microbial decomposition rate are both reduced, leading to a significant decrease in $CO₂$ produced in the soil [\(Fig. 3](#page-2-2)C). Thus, there is a decrease in $CO₂$ dissolved into groundwater, leading to a decrease in $pCO₂$ of the Furong Cave [\(Fig. 3](#page-2-2)B). Drought leads to less soil infiltration [\(Li et al., 2013](#page-7-34)), slower migration velocity of groundwater in the epikarst zone, longer residence time of groundwater in bedrock, and stronger water-rock interactions between water and bedrock [\(Fig. 7](#page-6-37)). As a result, more bedrock with a $\delta^{13}C$ value of −2.6–0.1‰ is dissolved into groundwater ([Li et al., 2012](#page-7-27)), leading to a higher $\delta^{13}C_{\text{DIC}}$ of drip water, and as a result, a lower mean $\delta^{13}C_{\text{DIC}}$ in the summer-autumn half of the year than in the winter-spring half of the year [\(Fig. 6](#page-4-0)). In addition, an extended drought can empty the fractures/cracks in the epikarst zone through a lack of sufficient water supply and can strengthen the degassing of groundwater in the epikarst

zone ([Fig. 7](#page-6-37)). A continuous winter-spring drought climate occurred in southwest China from 2009 to 2013 ([Hu et al., 2014](#page-7-39); [Wang et al.,](#page-7-40) [2015\)](#page-7-40), which led to the value of the $\delta^{13}C_{\rm DIC}$ of drip water in the Furong Cave being as high as 1.2‰ (MP1 drip water collected in January 2011) ([Fig. 3](#page-2-2)A). A significantly higher $\delta^{13}C_{\text{DIC}}$ of karst groundwater, due to the drought climate enhanced water-rock interaction, has also been confirmed in the Guizhou province in southwest China [\(Zhao et al.,](#page-7-41) [2015\)](#page-7-41).

In addition, the cave $pCO₂$ can affect the $CO₂$ of cave water to some degree. When $pCO₂$ of the cave air is high, the degassing of water $CO₂$ is suppressed, and vice versa ([Baker et al., 1998;](#page-6-38) [Dreybrodt, 1999](#page-6-39); [Genty](#page-6-10) [et al., 2001](#page-6-10); [Baldini et al., 2008](#page-6-17); [Li et al., 2011a](#page-7-42)). In the winter and spring seasons, the $pCO₂$ of the Furong Cave decreased [\(Fig. 3D](#page-2-2)), promoting the degassing of drip water $CO₂$, and thus, enriching the $\delta^{13}C_{\text{DIC}}$ of drip water [\(Fig. 7](#page-6-37)).

The range of variation in seasonal mean $\delta^{13}C_{\text{DIC}}$ values of drip water from the Furong Cave was −5.9 to −11.8‰ during 2009–2016 ([Fig. 6](#page-4-0)). This was higher than that from the caves in Gibraltar, Italy, Austria, Germany, France, and the United States (variation range of −8 to −16‰) [\(Spötl et al., 2005](#page-7-6); [Mattey et al., 2010;](#page-7-32) [Frisia et al., 2011](#page-6-4); [Riechelmann et al., 2011](#page-7-43); [Tremaine et al., 2011;](#page-7-25) [Peyraube et al., 2013](#page-7-44); [Meyer et al., 2014](#page-7-28)). Kinetic effects associated with $CO₂$ degassing are considered to be the primary factor responsible for positive deviation in $\delta^{13}C_{\text{DIC}}$ values of cave drip water from Europe and North America in winter and summer ([Meyer et al., 2014\)](#page-7-28). [Li et al. \(2012\)](#page-7-27) also suggested that a similar kinetically-enhanced process probably operates in the Furong Cave. Therefore, the hydrological conditions in the epikarst zone have changed because of the winter-spring drought climate between 2009 and 2013. Changes in hydrological conditions in the epikarst zone may have a more important effect on $\delta^{13}C_{\text{DIC}}$ values of groundwater than the kinetic effects in the cave. The response of δ^{13} C_{DIC} values to the change in precipitation illustrates that the signals of extreme climate can be transferred into the drip water in the Furong Cave. Higher $\delta^{13}C_{\text{DIC}}$ values of drip water correlated with drought conditions will be used to explain the high δ^{13} C values (range from −5‰ to 1‰) of stalagmite FR0510-1 in the Furong Cave, which are out of the δ¹³C range (−12‰ to −6‰) in the area dominated by C3 plants ([Li et al., 2011a\)](#page-7-42).

6. Conclusion

Based on continuous monitoring both inside and outside of the Furong Cave, from 2009 to 2016, this study found that temperature and precipitation determine the intensity of land surface biological activity and the yield of soil $CO₂$, which further affects the $pCO₂$ of cave air and the $\delta^{13}C_{\text{DIC}}$ of cave drip water. Although subject to soil and bedrock thickness, the peak pCO_2 of cave air lags behind that of soil pCO_2 by approximately 1–2 months. However, cave $pCO₂$ records the characteristics of seasonal variability in surface precipitation. On the interannual time scale, the higher $\delta^{13}C_{\text{DIC}}$ of cave drip water corresponds to less annual precipitation, and the lower $\delta^{13}C_{\text{DIC}}$ of cave drip water corresponds to more annual precipitation. This result suggests that the $\delta^{13}C_{\text{DIC}}$ of cave drip water can be used as an index of regional precipitation to reflect drought and flood events.

Acknowledgements

The editor Michael Kersten and two anonymous reviewers are greatly appreciated for their very professional and instructive comments and for providing suggestions to improve the manuscript. Li), the Fundamental Research Funds for the Central Universities grants, Southwest University (XDJK2014C010 and SWU114022 to J.-Y. Li and XDJK2017A010 to T.-Y. Li), and the Doctor Research Fund of Guizhou Normal University in 2016 to Dayun Zhu.

Fig. 7. Conceptual model demonstrating the link between temperature, precipitation, soil pCO_2 , cave air pCO_2 , and drip water $\delta^{13}C_{\text{DIC}}$. With a scenario of high temperature and more precipitation, such as in the summer monsoon months in this study (A). With a scenario of low temperature and less precipitation, such as in the winter and spring months in this study; no summer monsoon precipitation (B). This correlation is also suitable for the special scenario of summer drought, i.e., high temperature and less precipitation, such as in July 2011, August 2012, and July 2013 in this study.
